FastAPI — Building Robust APIs

Inventory Management System • End-to-End Project

Topics Covered in This Chapter

3.1 Setting Up the FastAPI Inventory Project
3.2 Building Data Models with Pydantic Validation
3.3 Exception Handling Strategies
3.4 Implementing Structured Responses and Documentation

Chapter 3: FastAPI — Building Robust APIs

FastAPI is a modern, high-performance Python web framework for building APIs with automatic interactive documentation. It is built on top of Starlette (for the web) and Pydantic (for data validation), making it one of the fastest Python frameworks available — comparable to NodeJS and Go in throughput.

In this chapter, we build a complete, production-style Inventory Management System from the ground up using FastAPI. This project covers every layer of a real backend application: project structure, database integration, data validation, error handling, and response standardisation.

What You Will Build

A fully functional REST API for inventory management.
The system tracks products, warehouse storage locations, and real-time inventory levels.
The architecture follows a modular, scalable pattern suitable for production deployment.

3.1 Setting Up the FastAPI Inventory Project

Section I — Theory

Before writing a single line of business logic, a well-structured project foundation saves significant time and technical debt down the road. This section walks through the decisions and patterns you need to set up a production-ready FastAPI project.

3.1.1 Why Project Structure Matters

FastAPI imposes no mandatory project layout — it is intentionally flexible. However, for any application that will evolve beyond a simple script, a carefully chosen structure brings three fundamental benefits:

- Separation of Concerns: Each module has a clearly defined responsibility. A database model lives in `db/`, an endpoint lives in `routers/`, and validation logic lives in `schemas/`
- Easier Debugging & Testing: When a bug occurs, you know exactly which layer is responsible. Tests can target individual modules without spinning up the entire app.
- Team Scalability: Multiple engineers can work on products, locations, and inventory endpoints simultaneously without stepping on each other's files.

3.1.2 Recommended Directory Layout

The following structure is used throughout this chapter and mirrors the layout of many production FastAPI applications:

Directory / File	Purpose
app/db/	Database models (SQLAlchemy ORM classes) and connection/session setup
app/crud/	Repository classes — all Create, Read, Update, Delete logic lives here

app/routers/	API endpoint handlers grouped by domain (products, locations, inventory)
app/schemas/	Pydantic models for request validation and response serialization
app/core/	Cross-cutting concerns: exceptions, settings, security, middleware
management/	Utility scripts such as database initialisation (inventory_tools.py)
.env	Environment variables for local development (never committed to Git)
requirements.txt	Python package dependencies
main.py	Application entry point — creates the FastAPI instance and mounts routers

3.1.3 Environment Configuration

Every real application needs configuration that changes between environments (development, staging, production). The two most common values are database connection strings and secret keys.

- Development: Store these in a `.env` file and load them using the `python-dotenv` library.
- Production: Never use a plain `.env` file. Use your cloud provider's secret manager (AWS Secrets Manager, GCP Secret Manager, Azure Key Vault) or inject environment variables at the container level.

3.1.4 Database Design

The application uses SQLite during development — a file-based database that requires zero configuration. In production, you would swap this connection string for PostgreSQL or MySQL with no change to the application code, which is one of the great advantages of using SQLAlchemy as an ORM.

The system is built around three core tables:

Table	Key Columns	Purpose
Product	id (PK), name, sku (UNIQUE), price	Master catalogue of all products
Location	id (PK), name, address, capacity	Warehouses or storage zones
InventoryItem	product_id (FK), location_id (FK), quantity, reorder_point	Junction table tracking stock of each product at each location

The InventoryItem table uses a composite primary key (product_id, location_id), which means each product can exist in multiple locations and each location can hold multiple products — a classic many-to-many relationship resolved through a junction table.

3.1.5 FastAPI's Auto-Generated Documentation

One of FastAPI's killer features is automatic, interactive API documentation generated from your code and type annotations — with zero extra effort.

- Swagger UI: Available at `/docs`. Fully interactive — you can execute requests directly from the browser.
- ReDoc: Available at `/redoc`. A clean, read-only documentation view ideal for sharing with stakeholders.

Section II — Practical Implementation

Step 1 — Create and Activate a Virtual Environment

A virtual environment isolates your project's Python packages from the system-level Python installation. This prevents version conflicts between projects.

```
# Create the virtual environment
python -m venv venv

# Activate on Windows
venv\Scripts\activate

# Activate on macOS / Linux
source venv/bin/activate
```

Why Virtual Environments?

Without a virtual environment, all projects share the same Python packages.
If Project A needs fastapi==0.95 and Project B needs fastapi==0.110, they will conflict.
A virtual environment gives each project its own isolated package space.

Step 2 — Define and Install Dependencies

List all project dependencies in a requirements.txt file. This file becomes the single source of truth for anyone who clones your repository.

```
# requirements.txt
fastapi==0.110.0
uvicorn[standard]==0.29.0
sqlalchemy==2.0.29
pydantic==2.6.4
python-dotenv==1.0.1
aiosqlite==0.20.0
```

```
# Install all dependencies in one step
pip install -r requirements.txt
```

Step 3 — Initialize the Database

Before starting the API, run the database initialization script to create the tables:

```
# Run from the project root
python management/inventory_tools.py
```

Step 4 — Create the Application Entry Point (main.py)

This is the heart of the application. The main.py file creates the FastAPI instance, mounts all routers, and starts the server. Every line here is explained below.

```
# main.py
```

```
from fastapi import FastAPI                    # (1) Import the FastAPI class
from app.routers import routers                # (2) Import all registered routers

# (3) Create the FastAPI application instance
#     The metadata here powers the auto-generated /docs page
app = FastAPI(
    title="Inventory Management API",
    description="API for managing inventory across multiple warehouse locations",
    version="1.0.0"
)

# (4) Mount every router onto the main application
#     Routers group related endpoints (products, locations, inventory)
for router in routers:
    app.include_router(router)

# (5) Health check endpoint
#     Always include this in production — used by load balancers and monitoring
tools
@app.get("/health", tags=["Health"])
async def health_check():
    """Verify that the API server is running and reachable."""
    return {
        "status": "online",
        "message": "Inventory Management API is running"
    }

# (6) Development server entry point
#     In production, you would use: uvicorn main:app --host 0.0.0.0 --port 8000
if __name__ == "__main__":
    import uvicorn
    uvicorn.run("main:app", host="0.0.0.0", port=8000, reload=True)
```

Let us break down every numbered comment:

- (1) FastAPI is the main class. Instantiating it creates your ASGI application object.
- (2) We import a list of routers from `app/routers/__init__.py`. This pattern keeps main.py minimal — it does not need to know about individual endpoints.
- (3) The title, description, and version populate the /docs header automatically. Never leave these blank on a real project.
- (4) `app.include_router(router)` registers each router's endpoints with the main app. Looping over a list makes adding new routers a one-line change.
- (5) The `/health` endpoint is a production standard. Cloud load balancers (AWS ALB, GCP Load Balancer) ping this endpoint to decide whether to route traffic to this instance.
- (6) `reload=True` enables hot-reloading during development — the server restarts automatically when you save a file. Disable this in production.

Step 5 — Run the Server

```
# Start the development server
python main.py

# Alternatively, run uvicorn directly:
```

```
uvicorn main:app --reload --host 0.0.0.0 --port 8000

# Visit these URLs in your browser:
# API:       http://localhost:8000
# Swagger:   http://localhost:8000/docs
# ReDoc:     http://localhost:8000/redoc
# Health:    http://localhost:8000/health
```

3.2 Building Data Models with Pydantic Validation

Section I — Theory

With the project skeleton in place, the next step is to build the API's data layer — the routers that handle HTTP requests and the Pydantic models that validate the data flowing through those requests.

3.2.1 Modular API Routers

In a monolithic FastAPI file, all endpoints exist in a single file — manageable for toy projects but unmaintainable at scale. FastAPI's APIRouter allows you to split endpoints into separate modules, each with its own URL prefix and Swagger tag group.

Think of APIRouter like a mini FastAPI application. You define routes on it exactly as you would on the main app object, but they are registered under a common URL prefix. When your application grows, you can even extract a router into its own microservice with minimal refactoring.

3.2.2 What is Pydantic?

Pydantic is the data validation engine that powers FastAPI's request and response handling. When a client sends a JSON body to your API, FastAPI automatically passes it through your Pydantic model before your route function even runs. If the data is invalid, FastAPI returns a detailed 422 Unprocessable Entity response — no custom error handling required.

Pydantic Feature	What it Does
Type Validation	Ensures a field declared as int cannot receive a string
Type Coercion	Automatically converts '42' (string) to 42 (int) where safe
Field Constraints	Enforces min/max length, numeric bounds, regex patterns
Custom Validators	Run arbitrary Python code against a single field or the entire model
Serialization	Converts Python objects to JSON-serializable dictionaries for responses
Schema Generation	Produces JSON Schema, which FastAPI uses to build /docs

3.2.3 The Schema Design Pattern

A common mistake is to use the same Pydantic model for both input (creation) and output (response). This is problematic because:

- Your creation model should never include the id (the database generates it).
- Your response model might exclude sensitive internal fields.
- Update models may have all fields optional (partial update / PATCH pattern).

The recommended pattern is to define purpose-specific models:

Schema Class	HTTP Operation	Contains

ProductCreate	POST	All fields required to create a product. No id field.
ProductUpdate	PUT / PATCH	All fields optional. Client sends only what changes.
ProductResponse	All responses	What the API returns. Includes id and computed fields.

3.2.4 Field-Level vs Model-Level Validation

Pydantic supports two levels of validation:

- Field validators `(@field_validator)`: Run against a single field in isolation. Use these for format checks (SKU regex, price bounds, string length).
- Model validators `(@model_validator)`: Run against the entire model after all fields have been validated. Use these for cross-field business rules (e.g., a large stock reduction requires a reason).
- mode='before': Runs before Pydantic's type conversion. Useful for preprocessing raw strings (e.g., strip whitespace, normalize case).
- mode='after': Runs after all field validations pass. Useful for business rule enforcement that requires multiple validated fields.

3.2.5 Dependency Injection and Database Sessions

FastAPI's Depends() system is its dependency injection mechanism. Instead of creating a database session manually inside every route function, you define a generator function (get_db) that creates a session, yields it to the route, and then closes it — even if an exception occurs.

This pattern guarantees that database connections are always properly returned to the connection pool, preventing resource leaks in production.

Section II — Practical Implementation

Step 1 — Create the Routers Directory and Files

```
# Create the router modules
# Each file handles one domain of the API
app/
  routers/
     __init__.py      # Collects and exports all routers
    products.py       # /products endpoints
    locations.py      # /locations endpoints
    inventory.py      # /inventory endpoints
```

Step 2 — Implement the Products Router (products.py)

```
# app/routers/products.py

from fastapi import APIRouter, Depends, status
from sqlalchemy.orm import Session
from typing import Optional, List

from app.db.session import get_db            # DB session dependency
from app.crud.product import product_repository  # CRUD layer
```

```
from app.schemas.product import ProductCreate, ProductResponse

# (1) Create the router with a URL prefix and Swagger tag
router = APIRouter(
    prefix="/products",
    tags=["Products"]
)

# (2) GET all products — supports search and pagination
@router.get("/", response_model=List[ProductResponse])
def list_products(
    search: Optional[str] = None,    # Optional keyword search
    skip: int = 0,                   # Pagination offset
    limit: int = 100,                # Maximum records to return
    db: Session = Depends(get_db)    # Injected DB session
):
    """Retrieve a paginated list of products with optional search filtering."""
    if search:
        return product_repository.search(db, search, skip=skip, limit=limit)
    return product_repository.get_all(db, skip=skip, limit=limit)

# (3) POST — create a new product
@router.post("/", response_model=ProductResponse, status_code=201)
def create_product(
    product: ProductCreate,          # Pydantic validates the request body
    db: Session = Depends(get_db)
):
    """Create a new product in the catalogue."""
    return product_repository.create(db, product)
```

Code walkthrough:

- (1) `prefix="/products"` means every route defined on this router will be accessible under /products. For example, the `"@router.get(\"/\")"` decorator creates the endpoint GET /products/.
- (2) `Depends(get_db)` tells FastAPI to call get_db and inject the result as the db parameter. FastAPI calls get_db once per request and closes the session after the response is sent.
- (3) `response_model=ProductResponse` filters the output — even if the database model contains extra fields (like internal timestamps), only fields defined in ProductResponse are returned to the client.

Step 3 — Database Session Dependency

```
# app/db/session.py

from sqlalchemy import create_engine
from sqlalchemy.orm import sessionmaker

DATABASE_URL = "sqlite:///./inventory.db"

engine = create_engine(
    DATABASE_URL,
    connect_args={"check_same_thread": False}  # Required for SQLite
)
```

```
SessionLocal = sessionmaker(autocommit=False, autoflush=False, bind=engine)

def get_db():
    """
    FastAPI dependency that provides a database session per request.
    The session is always closed in the finally block, even if an
    exception occurs mid-request. This prevents connection leaks.
    """
    db = SessionLocal()  # (1) Create a new session
    try:
        yield db         # (2) Provide session to the route function
    finally:
        db.close()       # (3) Always runs — cleans up the connection
```

Step 4 — Define Pydantic Schemas (schemas/product.py)

```
# app/schemas/product.py

from pydantic import BaseModel, Field, field_validator, model_validator
from typing import Optional
import re

# ── Creation Schema ──────────────────────────────────────────────
class ProductCreate(BaseModel):
    """Schema for validating product creation requests."""

    # Field(...) means required. min_length/max_length are enforced automatically.
    name: str = Field(..., min_length=1, max_length=100)
    description: Optional[str] = None
    sku: str = Field(..., min_length=5, max_length=9)
    price: float = Field(..., gt=0)   # gt=0 means 'greater than zero'

    # ── Field-Level Validators ──────────────────────────────────────
    @field_validator('sku')
    @classmethod
    def validate_sku(cls, v):
        """
        Enforce SKU format: CATEGORY-NUMBER (e.g., TECH-001, BOOK-042).
        Also normalises to uppercase.
        """
        if not re.match(r'^[A-Z]+-\d+$', v.upper()):
            raise ValueError('SKU must follow CATEGORY-NUMBER format (e.g., TECH-
001)')
        return v.upper()  # Normalise to uppercase

    @field_validator('name')
    @classmethod
    def validate_name(cls, v):
        """Reject product names containing special characters."""
        forbidden = ['@', '#', '$', '%', '&']
        for char in forbidden:
            if char in v:
                raise ValueError(f'Name cannot contain special character: {char}')
        return v

    @field_validator('price')
    @classmethod
    def validate_price(cls, v):
        """Round price to 2 decimal places and enforce a maximum."""
```

```
        v = round(v, 2)
        if v > 10000:
            raise ValueError('Price cannot exceed $10,000')
        return v

# ── Response Schema ──────────────────────────────────────────────
class ProductResponse(BaseModel):
    """Schema for all product API responses."""

    id: int = Field(..., description="Unique product identifier")
    name: str = Field(..., description="Product display name")
    description: Optional[str] = Field(None, description="Product description")
    sku: str = Field(..., description="Stock Keeping Unit code")
    price: float = Field(..., description="Product price in USD")

    # This config enables automatic conversion from SQLAlchemy ORM objects
    model_config = {
        "from_attributes": True,
        "json_schema_extra": {
            "example": {
                "id": 1,
                "name": "Wireless Keyboard",
                "description": "Ergonomic wireless keyboard with long battery
life",
                "sku": "TECH-001",
                "price": 49.99
            }
        }
    }
```

Step 5 — Inventory Router with Cross-Field Validation

```
# app/schemas/inventory.py

from pydantic import BaseModel, Field, field_validator, model_validator
from typing import Optional

class InventoryUpdate(BaseModel):
    """Schema for updating inventory stock levels."""

    product_id: int = Field(..., gt=0)
    location_id: int = Field(..., gt=0)
    quantity_change: int    # Positive = add stock, Negative = remove stock
    reorder_point: Optional[int] = Field(None, ge=0)
    reason: Optional[str] = None  # Required for large stock reductions

    @field_validator('quantity_change')
    @classmethod
    def validate_quantity_change(cls, v):
        """Limit single transaction size to prevent data entry errors."""
        if abs(v) > 100000:
            raise ValueError('Quantity change cannot exceed 100,000 units in a
single transaction')
        return v

    # (1) Model validator runs AFTER all field validators pass
    @model_validator(mode='after')
    def validate_inventory_operations(self):
        """Enforce business rules that span multiple fields."""
        # Rule 1: Large reductions require an explanation
```

```
        if self.quantity_change and self.quantity_change < -50 and not
self.reason:
            raise ValueError('Stock reductions of more than 50 units require a
reason')
        # Rule 2: Very large changes (either direction) require a reason
        if self.quantity_change and abs(self.quantity_change) > 200 and not
self.reason:
            raise ValueError('Changes of more than 200 units require a detailed
reason')
        return self
```

- (1) `mode='after'` means the model validator runs after every field has been individually validated and coerced. This guarantees that `self.quantity_change` and `self.reason` already hold their correct Python types when the cross-field logic executes.

Step 6 — Register All Routers (routers/__init__.py)

```
# app/routers/__init__.py

# Import each router module and alias it for clarity
from app.routers.products import router as products_router
from app.routers.locations import router as locations_router
from app.routers.inventory import router as inventory_router

# Collect all routers into a single list
# main.py iterates this list and registers each one with app.include_router()
routers = [
    products_router,
    locations_router,
    inventory_router,
]
```

This pattern is the key to keeping main.py clean. Adding a new feature (e.g., a suppliers/ module) is a two-step change: create the router file, then add one import and one list entry here.

3.3 Exception Handling Strategies

Section I — Theory

In any real-world application, failures are not edge cases — they are expected events. A product will be queried that does not exist. A request will arrive that tries to remove more stock than is available. A database connection will occasionally time out. A robust API must handle all of these scenarios gracefully, returning clear, consistent, and secure error responses.

3.3.1 Why Proper Error Handling is Non-Negotiable

Without exception handling, FastAPI returns a bare HTTP 500 Internal Server Error response with a generic message whenever an unhandled Python exception occurs. This is harmful for three reasons:

- Users receive no actionable information about what went wrong.
- Internal implementation details (stack traces, database schemas) may leak to external clients.
- Debugging becomes difficult because errors are not categorised or logged consistently.

3.3.2 Exception Handling Architecture

A layered exception handling strategy works from the most specific to the most general:

Layer	Mechanism	Used For
Route-level	if/else + raise HTTPException	Simple resource-not-found checks
Custom Exceptions	Domain-specific exception classes	Business rule violations with rich context
Global Handlers	app.add_exception_handler()	Centralized formatting and logging for all exception types

3.3.3 HTTPException — FastAPI's Built-in Tool

For simple scenarios, FastAPI's built-in HTTPException is the right tool. When you raise it, FastAPI automatically formats the response as JSON with the correct HTTP status code. The detail field can be a string or a dictionary — use a dictionary when you want to include contextual information alongside the error message.

3.3.4 Custom Exception Hierarchy

As applications grow, you need exceptions that carry domain-specific context. A bare HTTPException with a status code and message is not enough — a stock shortage error should know which product is affected, how much was requested, and how much is available.

The recommended pattern is a base exception class that carries a status_code, message, and details dictionary. Domain-specific exceptions inherit from this base class and populate those fields with meaningful data.

3.3.5 Global Exception Handlers

Global handlers are async functions registered with the FastAPI application that intercept exceptions of a specific type — anywhere in the application — and return a standardised JSON response. This means your route functions can raise exceptions freely without worrying about formatting the error response themselves.

Three global handlers should exist in every production FastAPI application:

1. InventoryError handler — catches all custom business exceptions.
2. SQLAlchemyError handler — catches database-level errors and returns a safe 500 response without exposing the raw SQL error.
3. General Exception handler — the catch-all safety net for any unhandled exception that escapes the two handlers above.

Section II — Practical Implementation

Step 1 — Custom Exception Hierarchy (core/exceptions.py)

```
# app/core/exceptions.py

class InventoryError(Exception):
    """
    Base exception class for all inventory business logic errors.
    All custom exceptions should inherit from this class so that
    the global handler can catch them with a single registration.
    """
    status_code: int = 500   # Default; subclasses override this

    def __init__(self, message: str, details: dict = None):
        self.message = message
        self.details = details or {}
        super().__init__(self.message)

class RecordNotFoundError(InventoryError):
    """Raised when a requested record does not exist in the database."""
    status_code = 404

    def __init__(self, record_type: str, record_id: int):
        message = f"{record_type} with id {record_id} not found"
        details = {
            "record_type": record_type,
            "record_id": record_id
        }
        super().__init__(message, details)

class InsufficientStockError(InventoryError):
    """Raised when a stock removal would result in negative inventory."""
    status_code = 400

    def __init__(self, product_id: int, requested: int, available: int):
        message = f"Insufficient stock for product {product_id}"
        details = {
            "product_id": product_id,
            "requested": requested,    # How much the client tried to remove
            "available": available     # How much actually exists
        }
        super().__init__(message, details)
```

Step 2 — Using Custom Exceptions in the CRUD Layer

```
# app/crud/inventory.py (excerpt)

from app.core.exceptions import RecordNotFoundError, InsufficientStockError
```

```python

class InventoryRepository:

    def update_stock(
        self, db: Session,
        product_id: int, location_id: int,
        quantity_change: int,
        reorder_point: Optional[int] = None
    ):
        # (1) Verify the product exists — raise if not
        product = db.query(Product).filter(Product.id == product_id).first()
        if not product:
            raise RecordNotFoundError("Product", product_id)

        # (2) Fetch or create the inventory record
        inventory_item = self.get(db, product_id, location_id)
        if not inventory_item:
            if quantity_change <= 0:
                return None   # Cannot create a negative inventory record
            # Auto-create the inventory record for this product-location pair
            inventory_item = InventoryItem(
                product_id=product_id,
                location_id=location_id,
                quantity=0
            )
            db.add(inventory_item)

        # (3) Prevent stock from going negative
        new_quantity = inventory_item.quantity + quantity_change
        if new_quantity < 0:
            raise InsufficientStockError(
                product_id=product_id,
                requested=abs(quantity_change),
                available=inventory_item.quantity
            )

        inventory_item.quantity = new_quantity
        db.commit()
        db.refresh(inventory_item)
        return inventory_item
```

Step 3 — Global Exception Handlers (core/error_handlers.py)

```python
# app/core/error_handlers.py

from fastapi import Request
from fastapi.responses import JSONResponse
from sqlalchemy.exc import SQLAlchemyError

from app.core.exceptions import InventoryError

async def inventory_exception_handler(request: Request, exc: InventoryError):
    """
    Handles all custom business exceptions that inherit from InventoryError.
    Returns a consistent JSON structure with error context.
    """
    return JSONResponse(
        status_code=exc.status_code,
        content={
            "error": True,
```

```
            "message": exc.message,
            "details": exc.details
        }
    )

async def sqlalchemy_exception_handler(request: Request, exc: SQLAlchemyError):
    """
    Handles database-level errors.
    Logs the full error internally but returns only a safe generic message
    to the client — never expose raw SQL errors externally.
    """
    print(f"Database error: {str(exc)}")  # Replace with proper logging in prod
    return JSONResponse(
        status_code=500,
        content={
            "error": True,
            "message": "A database error occurred",
            "details": {
                "error_type": exc.__class__.__name__,
                "error": "The operation couldn't be completed due to a database
issue"
            }
        }
    )

async def general_exception_handler(request: Request, exc: Exception):
    """
    Catch-all handler for any unhandled exceptions.
    Never expose internal error details to clients in production.
    """
    print(f"Unexpected error: {str(exc)}")
    return JSONResponse(
        status_code=500,
        content={
            "error": True,
            "message": "An unexpected error occurred",
            "details": {
                "error_type": exc.__class__.__name__
                # Do NOT include str(exc) here — it may contain sensitive info
            }
        }
    )
```

Step 4 — Register Global Handlers in main.py

```
# main.py (updated)

from fastapi import FastAPI
from sqlalchemy.exc import SQLAlchemyError

from app.routers import routers
from app.core.exceptions import InventoryError
from app.core.error_handlers import (
    inventory_exception_handler,
    sqlalchemy_exception_handler,
    general_exception_handler
)

app = FastAPI(title="Inventory Management API", version="1.0.0")
```

```
# Register global exception handlers
# Order matters: more specific handlers before the general catch-all
app.add_exception_handler(InventoryError, inventory_exception_handler)
app.add_exception_handler(SQLAlchemyError, sqlalchemy_exception_handler)
app.add_exception_handler(Exception, general_exception_handler)

for router in routers:
    app.include_router(router)
```

Security Note on Error Responses

Always log full exception details server-side (to your logging system) but return only generic messages to clients.
A stack trace returned to a client is a security vulnerability — it reveals your internal architecture.
The pattern here logs internally and returns sanitised JSON externally.

3.4 Implementing Structured Responses and Documentation

Section I — Theory

As APIs mature and get consumed by more clients (frontend teams, mobile apps, third-party integrations), returning raw database objects becomes increasingly problematic. Structured responses and rich documentation transform an API from a black box into a self-describing, reliable contract between the backend and its consumers.

3.4.1 The Problem with Raw Database Responses

When you return a SQLAlchemy model object directly from a route, FastAPI tries to serialize it automatically. This leads to several serious issues:

- Internal coupling: Your API's public shape becomes tightly coupled to your database schema. A column rename breaks all clients.
- Security risk: Internal fields (password hashes, internal IDs, audit timestamps) may leak to clients unintentionally.
- No documentation: Without an explicit response model, the /docs page cannot show clients what the response structure looks like.
- Serialization errors: SQLAlchemy objects with lazy-loaded relationships will cause RecursionError or DetachedInstanceError during serialization.

The solution is to always define explicit Pydantic response schemas and attach them to your routes via the response_model parameter.

3.4.2 API Documentation Best Practices

FastAPI generates documentation automatically, but the default output only shows bare parameter names and types. You can significantly improve the developer experience by enriching your endpoint definitions with metadata:

Documentation Element	How to Add It
Endpoint summary	summary= parameter in route decorator
Detailed description	description= parameter, or the function's docstring
Parameter descriptions	Query(description='...') wrapper instead of bare default value
Parameter constraints	Query(ge=0, le=100) adds min/max to the docs UI
Response examples	model_config with json_schema_extra in the Pydantic schema
Multiple response codes	responses= dict in route decorator, mapping status codes to descriptions

3.4.3 Documenting All Possible Responses

By default, FastAPI only documents the success response for an endpoint. In a real API, an endpoint may return several different status codes depending on what happens. Documenting all of these gives client developers a clear contract — they know exactly what to expect and handle.

For a GET /products/{product_id} endpoint, the full response contract should include:

4. 200 OK — Product found and returned as ProductResponse.
5. 404 Not Found — Product with the given ID does not exist.
6. 422 Unprocessable Entity — The product_id path parameter failed validation (e.g., was a string instead of an integer).

Section II — Practical Implementation

Step 1 — Define the ProductResponse Schema with Examples

```
# app/schemas/product.py

class ProductResponse(BaseModel):
    """
    Response schema for all product endpoints.
    This is what the API client receives — it is deliberately separate
    from ProductCreate to decouple the public API contract from the DB schema.
    """
    id: int = Field(..., description="Unique product identifier")
    name: str = Field(..., description="Product display name")
    description: Optional[str] = Field(None, description="Full product
description")
    sku: str = Field(..., description="Stock Keeping Unit code (e.g., TECH-001)")
    price: float = Field(..., description="Product price in USD")

    model_config = {
        # from_attributes=True allows Pydantic to read values from SQLAlchemy
        # ORM objects (via attribute access) instead of only from dicts.
        "from_attributes": True,
        "json_schema_extra": {
            "example": {
                "id": 1,
                "name": "Wireless Keyboard",
                "description": "Ergonomic wireless keyboard with long battery
life",
                "sku": "TECH-001",
                "price": 49.99
            }
        }
    }
```

Step 2 — Enrich the List Products Endpoint with Metadata

```
# app/routers/products.py

from fastapi import APIRouter, Depends, Query, status
from typing import Optional, List

@router.get(
    "/",
    response_model=List[ProductResponse],
    summary="List all products",
    description="Retrieve a paginated list of products with optional search
filtering."
)
def list_products(
    search: Optional[str] = Query(
        None,
        description="Search term for filtering products by name or SKU"
    ),
```

```
    skip: int = Query(
        0,
        ge=0,
        description="Number of rows to skip for pagination"
    ),
    limit: int = Query(
        10,
        ge=1,
        le=100,
        description="Number of records to retrieve (max 100)"
    ),
    db: Session = Depends(get_db)
):
    if search:
        return product_repository.search(db, search, skip=skip, limit=limit)
    return product_repository.get_all(db, skip=skip, limit=limit)
```

With the Query() wrappers in place, the Swagger UI now shows:

- A human-readable description for each parameter
- The default value pre-filled in the input field
- Validation constraints (minimum: 0, maximum: 100) displayed under the field
- Automatic validation — if a client sends limit=1000, FastAPI returns a 422 error before your function even runs

Step 3 — Document Multiple Response Codes

```
# app/routers/products.py

@router.get(
    "/{product_id}",
    response_model=ProductResponse,
    summary="Get product by ID",
    description="Retrieve detailed information about a specific product by its
ID.",
    responses={
        # (1) Success response — links to the Pydantic schema
        status.HTTP_200_OK: {
            "description": "Product found successfully",
            "model": ProductResponse
        },
        # (2) Not found — includes an example of the error body
        status.HTTP_404_NOT_FOUND: {
            "description": "Product not found",
            "content": {
                "application/json": {
                    "example": {
                        "error": True,
                        "message": "Product not found",
                        "details": {
                            "record_type": "Product",
                            "record_id": 123
                        }
                    }
                }
            }
        }
    }
)
def get_product(product_id: int, db: Session = Depends(get_db)):
```

```
    """Retrieve a single product by its database ID."""
    product = product_repository.get(db, product_id)
    if not product:
        raise RecordNotFoundError("Product", product_id)
    return product
```

The responses dictionary serves two purposes simultaneously:

- Documentation: The `/docs` page now shows a dropdown listing all possible response codes, each with its description and an example body. This is the API contract that your frontend team sees.
- Transparency: Client developers no longer need to guess what a 404 error looks like from this endpoint — the example is right there in the documentation.

Chapter Summary — Key Takeaways

1. Structure your FastAPI project modularly from Day 1 — routers, schemas, crud, and core are distinct layers.
2. Use Pydantic field validators for single-field rules and model validators for cross-field business logic.
3. Always define separate Create, Update, and Response schemas. Never expose your database model directly.
4. Build a custom exception hierarchy rooted in a base class for consistent, rich error context.
5. Register global handlers for your custom exceptions, SQLAlchemy errors, and general exceptions.
6. Enrich every endpoint with response_model, summary, description, and Query() metadata for self-documenting APIs.
7. Document all possible response codes — not just 200 OK — using the responses= parameter.
